Microglia are the brain's tissue macrophage and representative of the innate immune system. These cells normally provide tissue maintenance and immune surveillance of the brain. In the Alzheimer's disease brain, amyloid deposition provokes the phenotypic activation of microglia and their elaboration of proinflammatory molecules. Recent work has implicated Toll-like receptors in microglial recognition and response to amyloid fibrils. It is now evident that these cells exhibit more complex and heterogeneous phenotypes than previously appreciated that reflect both the plasticity of cells in this lineage and their ability to transition between activation states. The phenotypic diversity is associated with inactivation of the inflammatory response and tissue repair. We discuss recent evidence that the brain can be infiltrated by circulating monocytes in the diseased brain and that these cells may comprise a unique subpopulation of myeloid cells that may be functionally distinct from the endogenous microglia.

questions surrounding the biology of this enigmatic cell type. The purpose of this review is to highlight our new insight into the basic physiological actions of microglia and how they are perturbed during the course of Alzheimer’s disease. It is our intention to focus on newer controversies in the field. Specifically, how does the activation status of microglia influence their role in pathogenesis or prevention of Alzheimer’s disease, new findings on the participation of Toll-like receptors in AD pathogenesis, and the evidence for peripheral monocyte infiltration in the brain and their potential roles in mitigating the disease.

**Microglia—new insight into the biology of the brain’s tissue macrophage**

Microglia are the brain’s tissue macrophage (Ransohoff and Perry, 2009). Many of the questions about their role in the AD brain are reliant upon knowledge of the origins and normal behaviors of these cells. Central amongst these questions are whether microglia are resident in the brain for the life span of the organism, whether they normally renew themselves through proliferation within the brain or whether myeloid progenitors normally infiltrate the brain to replace senescent cells. For some of these questions, we still only have tentative answers. These questions have largely been only of academic interest until recently when it has been proposed that monocytes in the peripheral circulation immigrate into the mature brain, particularly in the course of neurodegenerative diseases such as AD, which has clear therapeutic implications. The ensuing controversy has now focused attention on the origins of parenchymal microglia in both the developing and the mature brain (Chan et al., 2007).

During development, microglial progenitors, derived from mesenchymal myeloid lineage progenitor cells, immigrate into the embryonic brain early in gestation (Chan et al., 2007). They proliferate in situ and exhibit a motile ameboid phenotype, populating the brain before the development and closure of the blood–brain barrier. This population is thought to be distinct from fetal macrophages that are also myeloid in origin but arise from monocytes in the fetal circulation. These fetal macrophages also invade the developing brain and contribute to the microglial population, particularly at later developmental times (Streit et al., 2004). The lack of distinguishing lineage markers has prevented any hard conclusions to be drawn on the relative contribution of these different myeloid cells to the microglia population in the mature brain.

The microglia, like other tissue macrophages, acquire a tissue-specific phenotype that is reflective of local environmental influences. A corollary is that within a single tissue, these cells can exhibit a diverse range of phenotypic characteristics, owing to the different cellular composition and physiology of a complex tissue such as the brain. Macrophages are extraordinarily plastic and are able to dramatically alter their phenotype and exhibit a remarkable array of behaviors and morphologies in response to environmental stimuli. In the mature brain, the microglia extend ramified processes into the surrounding tissue. Importantly, in the normal brain, the interaction of microglia with both neurons and other glia serves to suppress the ‘activation’ of the cells and dampen their response to proinflammatory signals and spurious induction of an immune response (Colton, 2009). Pairs of receptors that are uniquely expressed by microglia and other neural cell types mediate these interactions. For example, fractalkine is a membrane glycoprotein expressed on the neuronal cell surface and interacts with the chemokine receptor CX3CR1 on the microglia (Ransohoff et al., 2007). The interaction of these two cell types, during the course of microglial surveillance of the brain, acts to suppress microglia activation in the normal brain (Cardona et al., 2006). Neurons also express CD200 on their cell surface that interacts with its corresponding ligand, CD200L, on microglia. The CD200–CD200L interaction acts to inhibit the production of proinflammatory mediators by microglia. CD200 and CD200R levels are reduced in the cortex and hippocampus of AD patients, compared to age-matched controls (Walker et al., 2009). It is of particular interest that CD200 expression is positively regulated by the anti-inflammatory cytokine IL-4 (Lyons et al., 2007). There is good evidence that the reciprocal interaction of the receptor pair signal regulatory protein α (SIRPα; SHPS-1) and CD47 signals bidirectionally to both cell types. SIRPα is expressed on myeloid cells, astrocytes, and neurons (Adams et al., 1998; Kusakari et al., 2008) and CD47 is expressed by both microglia and neurons (Matozaki et al., 2009). The effect of neuronal CD47 upon its association with microglial SIRPα is to suppress microglial proinflammatory cytokine expression and inhibit phagocytosis (Matozaki et al., 2009).

Streit et al. (2004) have argued that in humans (but not rodents), microglia normally senesce and undergo microglial dystrophy that, in some cases, involves a process of cytorrhesis. While this latter process can be observed in normal aging brains, it is more frequently observed in neurodegenerative diseases. Floden and Combs (2006) have reported that microglia derived from aged animals exhibit a distinct different response to fibrillar Aβ compared to those from neonates. A recent study examining the behaviors of microglia by two-photon microscopy in the living brain of murine models of AD found that microglia in the aged brain were less motile and possessed fewer processes (Meyer-Luehmann et al., 2008), supporting the view that aging is accompanied by impaired microglial functionality (Streit et al., 2008).

Microglia, in their roles as tissue macrophages, act normally to carry out tissue maintenance and immune surveillance. New insight into the normal biology of microglia has come from advanced imaging methods, allowing direct observation of microglia in the living brain. A series of remarkable studies has revealed that microglia continuously extend and retract processes into the adjacent tissue with a radius of about 80 μm (Nimmerjahn et al., 2005). Thus, the entire brain undergoes surveillance by these cells every few hours. The microglia sample their environment by macropinocytic uptake of the extracellular fluid and contact neurons, other glia, and vessels. Tissue damage elicits a rapid redirection of microglial processes to the area of damage and, if sustained, promotes the migration of the cell to the affected area (Davalos et al., 2005). Microglia also monitor synaptic activity, contacting each synapse about once per hour and acting to remodel functionally impaired synapses (Wake et al., 2009). Analysis of murine models of AD using these techniques has been quite illuminating, revealing that amyloid plaques form in the brain and become progressively larger, followed by the appearance of microglia that become associated with the plaque and which exhibit an ‘activated’ phenotype (Yan et al., 2009). Neuritic dystrophy is subsequently observed, although its cause is not known. These findings provide direct evidence that microglia detect and respond to amyloid deposition, which elicits the induction of an inflammatory phenotype. Bornemann et al. (2001) have reported that microglia proliferate in the brains of mice with deposited amyloid.

**Microglial activation in the AD brain**

There is an extensive literature documenting a microglial-mediated inflammatory response in the AD brain. This topic has been the subject of a number of reviews (Combs, 2009) and we will focus here on recent developments that shed new insight into the roles of inflammation and microglia in AD pathogenesis. It should be appreciated that the primary evolutionary pressure on this lineage has been host defense mechanisms, and they are quite efficient in mobilizing these responses. Indeed, microglia and macrophages express a panorama of cell surface receptors that they use alone, or in combination, to detect pathogens or foreign materials. Engagement of the host defense mechanisms provokes the conversion of a ‘resting’ microglia into an ‘activated’ phenotype that is associated with a robust and coordinated response involving the production of free
radicals and the generation and secretion of cytokines, chemokines, and acute-phase proteins. While this is an effective response for elimination of pathogens, it is maladaptive when these mechanisms are engaged by disease processes that originate within the tissue itself, especially in the CNS. In the AD brain, the formation of amyloid fibrils and their deposition elicits the phenotypic activation of microglia and the panoply of responses that accompany the activation of host defense mechanisms.

The advent of PET-based techniques that allow imaging of activated microglia in the living human brain has provided a new perspective on the how and when these cells are activated (Cagnin et al., 2007). The availability of carbon 11-labeled compounds that bind to the mitochondrial protein TP-18 (also termed the peripheral benzodiazepine receptor), which is expressed at elevated levels in activated microglia, has allowed direct visualization of phenotypically activated cells. Edison et al. (2008) recently reported that they detected an increased abundance of activated microglia in cortex of AD patients and this increase was not tightly correlated with overall amyloid plaque burden, but rather with reduced cognitive ability. However, a similar study failed to confirm these results (Wiley et al., 2009). Okello et al. (2009) reported that there was a correlation between diminished cognitive status and microglial activation in a subset of patients with mild cognitive impairment. The sensitivity of the method is limited by the radioligand employed in these studies. New compounds with better sensitivity are now available and may permit more definitive analyses (Doorduin et al., 2009). Analysis of murine models of AD using such a compound revealed a robust correlation of microglial activation and plaque deposition (Maeda et al., 2007). The elevated expression of TP-18 has also been reported in plaque-associated astrocytes (Ji et al., 2008).

The roles of Toll-like receptors in microglia in the AD brain

Microglia are the representatives of the innate immune system in the brain and possess a number of receptors, most prominently the Toll-like receptors (TLRs), through which they are able to detect microbial and viral pathogens and tissue damage (Bianchi, 2007; Palm and Medzhitov, 2009). Tissue damage results in the release of intracellular proteins that comprise ‘damage-associated molecular pattern’ molecules (DAMPs) that are detected by TLRs and other cell surface receptors and elicit an inflammatory response. Microbial pathogens express conserved pathogen-associated molecular patterns (PAMPs) that are common to microbes and allow their rapid and efficient recognition by the innate immune system primarily through TLRs that are specialized to recognize these molecules. Other pattern recognition receptors, which include the mannose receptor (CD206), scavenger receptors, C-type lectins, and their expression by the panoply of responses that accompany the activation of host defense mechanisms.

The advent of PET-based techniques that allow imaging of activated microglia in the living human brain has provided a new perspective on the how and when these cells are activated (Cagnin et al., 2007). The availability of carbon 11-labeled compounds that bind to the mitochondrial protein TP-18 (also termed the peripheral benzodiazepine receptor), which is expressed at elevated levels in activated microglia, has allowed direct visualization of phenotypically activated cells. Edison et al. (2008) recently reported that they detected an increased abundance of activated microglia in cortex of AD patients and this increase was not tightly correlated with overall amyloid plaque burden, but rather with reduced cognitive ability. However, a similar study failed to confirm these results (Wiley et al., 2009). Okello et al. (2009) reported that there was a correlation between diminished cognitive status and microglial activation in a subset of patients with mild cognitive impairment. The sensitivity of the method is limited by the radioligand employed in these studies. New compounds with better sensitivity are now available and may permit more definitive analyses (Doorduin et al., 2009). Analysis of murine models of AD using such a compound revealed a robust correlation of microglial activation and plaque deposition (Maeda et al., 2007). The elevated expression of TP-18 has also been reported in plaque-associated astrocytes (Ji et al., 2008).

The TLRs and the coreceptor CD14 and Aβ has been demonstrated through a variety of approaches, including co-incubation of Aβ and recombinant CD14, real-time surface plasmon resonance spectroscopy, and FLM-based FRET and antibody-mediated inhibition of the interaction (Reed-Geaghan et al., 2009). There is evidence that TLRs are involved in the microglial response to Aβ as inhibition of TLR4 or TLR2 through function blocking antibodies or siRNA knockdown also prevented Aβ-induced nitric oxide, IL-6, and TNF-α production (Jana et al., 2008; Udan et al., 2008; Walter et al., 2007). A recent study demonstrated a requirement of CD14, TLR 2 and 4 for Aβ-stimulated microglial responses (Reed-Geaghan et al., 2009). A mouse model of AD lacking functional TLR4 exhibited increased levels of the microglial marker CD11b and the reactive astrocyte marker GFAP (Jin et al., 2008). In addition, AD mice deficient for TLR2 were shown to have increased TGFB1 mRNA levels in plaque-associated microglia compared to wild type littermates (Richard et al., 2008). Treatment of microglia with TLR2, TLR4, or TLR9 ligands stimulates Aβ uptake in vitro (Tahara et al., 2006). However, this study did not discriminate whether this was due to phagocytosis or through other internalization mechanisms (Mandrekar et al., 2009) and this issue is of importance given that the internalized Aβ was found to be present in a spectrum of oligomer species, from monomers to very high MW forms. It should be noted that it has been reported that TLR9 activation in the presence of Aβ suppressed NO and TNFα release, whereas TLR2 and TLR4 ligands produced the opposite response (Lotz et al., 2005).

Role of TLRs in Aβ clearance

The TLRs and the coreceptor CD14 have been implicated in Aβ internalization by microglia (Liu et al., 2005b). Microglia require CD14 for phagocytic uptake of Aβ (Reed-Geaghan et al., 2009). Microglia exhibit the colocalization of CD14 and fibrillar Aβ42 at the cell surface, and they are then internalized and trafficked to the lysosome. Microglia lacking CD14 phagocytosed less fibrillar Aβ42 than did their wild type counterparts, though this was not due to general impairment of the phagocytic machinery. Both TLR2 and 4 are necessary for Aβ-stimulated phagocytosis (Reed-Geaghan et al., 2009).

The importance of TLR4 and TLR2 in Aβ uptake has also been evaluated in animal models of AD. The APPswe/PS1dE9 mouse model of Alzheimer’s disease (Jankowsky et al., 2004) is on a mixed genetic background which includes the CSH/Het strain. These animals possess a destructive point mutation in the TLR4 gene that prevents signaling from the mutant receptor (Poltorak et al., 1998). Tahara et al. (2006) employed this model to evaluate the role of TLR4 in...
amyloidogenesis in vivo. APPswe/PSEN1dE9 mice with inactive TLR4 exhibited increased cortical and hippocampal Aβ load when compared with mice with an intact TLR4 gene. These authors argued that the change in Aβ load was due to a change in microglial-mediated Aβ clearance that was reliant upon TLR4 function. In contrast, APPswe/PSEN1dE9 mice have been mated to TLR2/−/− mice, and the resulting transgenic TLR2/−/− mice showed delayed Aβ deposition through 6 months of age. Whether this is reflective of the roles of TLRs in Aβ clearance is unclear. It is noteworthy that the TLR2 null mice had comparable deposition by 9 months of age, compared to their TLR2+/+ littermates (Richard et al., 2008). The different results in Aβ deposition between TLR4− and TLR2−/− deficient animals could be explained by the age of the animals assessed. Jin et al. (2008) used mice that were aged at least 14 months, while Richard et al. examined their animals no later than 9 months of age. Hickman et al. (2008) have reported that the APPswe/PSEN1dE9 mouse has decreased expression of various Aβ-binding receptors and degrading enzymes at 8 months of age that accompanies an increase in proinflammatory gene expression. It is possible that microglia can efficiently clear Aβ in early stages of AD; however, at later stages in the disease, the genes involved in Aβ clearance are down-regulated, contributing to Aβ accumulation (Hickman et al., 2008).

Additional evidence for the roles of TLRs in Aβ clearance has been provided by Herber et al. (2004, 2006) who reported that intrahippocampal injection of the TLR4 ligand LPS into an animal model of AD resulted in clearance of diffuse, but not compact, Aβ plaques that were associated with microglial activation. Peripheral LPS administration resulted in cerebral microglial activation and a reduction in Aβ plaque burden (Quinn et al., 2003); however, it has also been reported that this treatment is associated with increased Aβ peptide levels (Sheng et al., 2003).

TLRs in Alzheimer’s disease have generally been thought to be necessary for recognition and clearance of the higher molecular weight Aβ species. TLRs evolved as a mechanism to recognize conserved PAMPs and DAMPs, and it has generally been thought that the monomeric and smaller oligomeric species of Aβ were unable to be recognized by these receptors. Recently, Scholtzova et al. (2009) demonstrated that activation of TLR9 by methyl CpG leads to a reduction in oligomeric Aβ species. This still only demonstrates that activation of microglia through TLRs can lower the Aβ load, and not that the oligomers themselves engage any specific receptor.

One of the principal unresolved questions in understanding the roles of microglia in the AD brain is why these cells fail to phagocytose and clear amyloid deposits in the brain. The literature is replete with demonstrations of the phagocytic capacity of these cells in vitro and immunotherapeutic studies have demonstrated that they can efficiently remove amyloid plaques from the brain when appropriately stimulated, likely through FcRs. At the moment, there is no clear understanding of why microglia fail to perform this basic function. Koenigsknecht-Talboo and Landreth (2005) reported that proinflammatory cytokine exposure was sufficient to functionally inactivate the phagocytic machinery. It remains unclear whether TLR actions on phagocytosis are selectively impaired and more work in this area is needed.

Alternative activation states of microglia

The microglial response to amyloid deposition in the brain has routinely been characterized as conversion of a ‘resting or quiescent’ phenotype into an ‘activated, proinflammatory’ phenotype. The latter phenotype has been linked with neurotoxicity and other deleterious effects in the brain, mostly coordinated through cytokines (Bodles and Barger, 2004). In the past few years, it has been appreciated that the response of microglia is more nuanced and complex than this dichotomy suggests (Colton, 2009). Moreover, the focus has been largely on the proinflammatory actions of the microglia and the vast majority of the literature documents these classical activation phenomena. Less attention has been paid to the resolution phase of the inflammatory response that engages mechanisms responsible for tissue maintenance and repair. The failure to appreciate the coordinated nature of the microglia/macrophage response whereby microglial activation is followed by induction of tissue repair mechanisms has contributed to the confusion over whether “inflammation” has positive or negative effects in the AD brain and other CNS disorders (Hansich and Kettenmann, 2007; Wyss-Coray and Mucke, 2002).

The classical activation of these cells is inferred by the induction of a number of cell surface proteins, most prominently receptors that participate in the innate immune response. The engagement of these host defense mechanisms, while effective in pathogen inactivation, produces collateral damage in the surrounding tissue. The classical activation is accompanied by the elaboration of chemokines, notably CCL2 (MCP-1), which mediate the recruitment and migration of microglia to amyloid deposits (El Khoury et al., 2007), where they invest the plaque with their processes. It is noteworthy that in the AD brain such classically activated microglia are associated with plaques throughout the disease process and are responsible for the proinflammatory milieu in the AD brain. Also, after exposure to amyloid, microglia are unable to express class II major histocompatibility complex (MHC II) which would be important in regulating any T-cell mediated response that occurs during the disease course (Butovsky et al., 2005; Town et al., 2005).

Microglia and other tissue macrophages exhibit a sophisticated and coordinated response through which the cells inactivate the initial immune response and initiate genetic programs that mediate tissue repair (Martinez et al., 2009). These mechanisms are associated with the production of anti-inflammatory cytokines. Most prominent amongst these are IL-4, IL-10, IL-13, and TGFβ which are produced by both glia and neurons and are associated with the conversion to other phenotypes, see Fig. 1 (Colton, 2009). These anti-inflammatory (Th2-type) cytokines are central to the development of what has been termed an “alternatively activated” state (also called M2) (Mantovani et al., 2004). However, the order, duration, and combinations in which microglia are exposed to stimulants may prove to be crucial in determining their response (Schwartz et al., 2006; Stout et al., 2005). Alternatively, activated macrophages are characterized by the suppression of Th1-proinflammatory cytokines, reduced NOS 2 expression, NOX2 activation, and induction of a number of genes that are characteristic on the acquisition of this phenotype. The conversion to an alternative activation state appears to be coordinated by two members of the peroxisome proliferator-activated receptor family, PPARγ and PPARβ/δ (Kang et al., 2008; Odegaard and Chawla, 2008; Odegaard et al., 2007; Odegaard et al., 2008), which act to regulate the program of gene expression that characterizes this macrophage phenotype (Gallardo-Soler et al., 2008). IL-4 receptor activation stimulates the generation of endogenous PPARγ ligands (Martinez et al., 2008) and the PPARγ gene . There is reciprocal response in which PPARγ activation in the brain is reported to result in elevated IL-4 levels (Loane et al., 2009).

Alternatively, activated murine macrophages express genes such as arginase 1, YM1, YM2, FIZZ1 (RELMy), and the mannose receptor (CD206) (Martinez et al., 2009). Indeed, IL-4 treatment of microglia stimulates the expression of these genes (Colton et al., 2006). This activation state has been termed M2. Colton et al. (2006) reported that these genes were also expressed at elevated levels in Tg2576 mice, a mouse model of AD, and in humans with AD. Maier et al. (2008) found that in aged hAPP-expressing mice lacking the complement factor C3 in the brain, the microglia exhibited an alternative activation phenotype, as evidenced by the reduced expression of NOS 2. These C3-deficient animals had increased IL-4 and IL-10 levels compared to those with the wild type allele. Also, IL-4 treatment of M2 microglia has been shown to lead to preferential
uptake and degradation of Aβ dimers and tetramers in vitro (Shimizu et al., 2008). Analysis of aged APP/PS1 mice by Jimenez et al. (2008) has yielded somewhat different results and interpretations. Examination of young animals found that microglia exhibited little expression of inflammatory cytokines, but YM1 expression was induced and marker-expressing microglia were associated with plaques. In older animals, there was increased expression of inflammatory cytokines and Nos 2, and these cells retained their expression of YM1, leading to the conclusion that the microglial phenotype changed from alternative to classic activation in this AD model. However, it is possible that the microglial population is functionally heterogeneous (see below).

A more detailed analysis of macrophage phenotypes has led to the identification of two distinct alternative activation states (Mantovani et al., 2004). The anti-inflammatory M2a state described above reflects the actions of IL-4 and IL-13. However, the anti-inflammatory actions elicited by IL-10 and TGFβ have a similar, but qualitatively and quantitatively distinct range of effects. This phenotype is termed ‘acquired deactivation’ or M2c and is associated with the robust suppression of the innate immune response, refer to Fig. 1. The acquired deactivation response is also elicited by exposure of macrophages to apoptotic cells. This is a highly evolved cellular response that allows the macrophage to detect apoptotic cells and ingest them without inducing a classical innate immune response. This allows normal developmental processes and accompanying patterned cell death as well as normal tissue maintenance to be performed without setting off an inflammatory response. Consequently, macrophages have evolved a number of mechanisms through which they can use receptors to detect cell surface phosphatidylserine molecules, either directly or through adapter proteins, which are uniquely found on apoptotic cells (Grommes et al., 2008). Engagement of these receptors simultaneously acts to suppress the activity of promoters of inflammatory genes, stimulate the expression of the anti-inflammatory cytokines IL-10 and TGFβ and stimulate phagocytosis, allowing removal of the cellular corpse from the tissue. There is recent evidence that the microglial Fcγ receptor expressed by myeloid cells 2, TREM2, plays analogous roles. TREM2 interacts with an undefined neuronal cell surface protein and this ligand–receptor interaction stimulates the uptake of apoptotic neurons and suppresses microglia inflammatory cytokine expression (Hsieh et al., 2009). TREM2 is expressed at elevated levels in an animal model of AD in plaque-associated microglia (Frank et al., 2008).

**Infiltration of the brain by peripherally derived monocytes**

There is a general consensus that endogenous microglia mediate a local inflammatory response upon exposure to Aβ and amyloid deposition in the AD brain and its murine models. However, this has recently been challenged by a number of recent studies that provide evidence that the brain is invaded by peripherally derived monocytes or macrophages (Rezai-Zadeh et al., 2009). The outcomes of these studies are provocative and have generated substantial controversy owing to a lack of agreement over the identification of peripherally derived mononuclear cells and experimental artifacts in some studies.

In the normal mature brain, the turnover of microglia is low, and these cells are renewed by proliferation of endogenous microglia (Ajami et al., 2007; Chan et al., 2007; Mildner et al., 2007). Infiltration of peripheral blood cells is normally prevented by the BBB. Specifically, the infiltration of peripheral monocytes into the normal brain is infrequent and the levels of these cells are very low. A number of CNS disorders, brain injury, or systemic infections (D'Mello et al., 2009) are accompanied by infiltration of the brain by peripheral monocytes, macrophages, or T lymphocytes. These cells migrate under the influence of cytokines and chemokines, most prominently CCL2. The role of invading peripherally derived monocytes in Alzheimer’s disease has recently received considerable attention and generated substantial controversy. Simard et al. (2006) reported that in the brains, murine models of AD were infiltrated by significant numbers of bone marrow-derived macrophages. These cells were found to be associated with amyloid plaques and were able to effectively phagocytose and clear Aβ deposits from the brain. Significantly, selective elimination of these cells by genetic and pharmacological manipulations resulted in increased plaque burden. These data were interpreted as evidence that the bone marrow-derived monocytes had a range of behaviors that distinguished them from resident microglia and raised the prospect that genetic manipulation of bone marrow progenitors might allow new therapeutic approaches to AD (Rivest, 2009). These experiments involved
the use of chimeric mice in which the host animal was irradiated and the bone marrow replaced with that of transgenic mice in which lineage markers or selection genes had been introduced. The host/transplant methodology has a number of confounds that were argued to have invalidated the conclusions from this study (Ransohoff, 2007). In a pair of complementary papers, Ajami et al. (2007) and Mildner et al. (2007) reported that the infiltration of the bone marrow-derived cells into the brain was an artifact of the chimeric host/transplant methodology. Indeed, studies using irradiated mice with transplanted fluorescently labeled bone marrow progenitors provided much of the rationale for this hypothesis (Malm et al., 2005; Stalder et al., 2005).

More compelling evidence was provided by studies of El Khoury et al. (2007) who reported the effects of knockout of the chemokine CCL2/MCP-1 receptor, Ccr2, in an animal model of AD. Myeloid lineage cells expressing this receptor migrate in response to the chemokine that is expressed at the site of injury, or in the case of AD, by plaque-associated microglia and astrocytes, thus accounting for the recruitment of microglia to these deposits. These authors proposed that this signaling system might be responsible for stimulating the infiltration of the brain by monocytes or macrophages from the peripheral circulation or by perivascular macrophages. Loss of Ccr2 expression was associated with many fewer microglia in the brain and increased Aβ levels. They argue that the increased numbers of monocytes/microglia in the brains of APP-expressing mice was due to infiltration of peripheral derived cells, based on the abundance of cells expressing high levels of CD45, a characteristic of this population that distinguishes them from endogenous microglia which have lower levels of CD45 expression. The magnitude of the effect was impressive with an approximate 8 fold increase in CD45hi cells (from 1% to 8% of total CD45-positive cells in the brain) and consistent with an overall 12-fold increase in the total number of microglia in the Tg2576 brain. However, the loss of Ccr2 in the APP-expressing mice was associated with microglia numbers roughly similar to that of wild type mice, owing to the impaired chemotaxis/migration of macrophages/microcytes. Town et al. (2008) have provided additional support for the notion that bone marrow-derived monocytes/macrophages immigrate into the parenchyma of the brain of animal models of AD and ameliorate AD-like pathology. These authors expressed a dominant negative form of the TGFβ1 receptor using a CD11c promoter and expressed in myeloid lineage cells. Contrary to their expectations, plaque pathology was dramatically less severe and behavior was improved in aged APP-expressing Tg2576 mice when TGFβ1 signaling was suppressed. Significantly, these latter mice exhibited increased numbers of plaque-related cells expressing CD45hi and other macrophage markers. The authors argue that the increase in CD45hi cells reflects the infiltration of the brain by blood-derived macrophages. However, they did not detect significant expression of the TGFβ1 receptor transgene in the brain and this is a potential confound in interpretation of the data given the magnitude of the increase in CD45hi-expressing cells.

The interpretation of both of these studies is reliant upon the fidelity of the markers employed. While the conclusions are reasonable if CD45 and CD11c expression is restricted to infiltrating cells and is unaltered for a significant period of time once the cells are resident in the tissue. Both of these genes are subject to acute regulation in this lineage and thus there remains a degree of uncertainty about the origin of these cells. Indeed, a subset of endogenous microglia has recently been reported to express CD11c, a canonical marker of dendritic cells (Bulloch et al., 2008). It will be important to establish exactly how many cells immigrate into the brain parenchyma, and the kinetics of this process. Also, it is of interest to know how long they remain in the tissue, whether they are trafficked out of the tissue or undergo apoptosis upon clearance of amyloid deposits and whether they exhibit sustained expression of the identifying markers.

Conclusions

As we have discussed, the response of microglia can vary along a spectrum of different states and some can be detrimental. Major questions remaining for the field, while not new, include whether or not peripheral monocytes are able to infiltrate the brain and alter the disease course in AD. Also, it will be important to determine whether the activation state of the resident microglia is different from the infiltrating monocytes. Furthermore, are there differentially activated microglia around the same plaques? Also, does the activation status of the microglia alter during the disease course and does their adaptability lessen as the organism ages? Therefore, the challenge in the development of future treatments will be not simply turning on or off the immune response, but tuning the dial so that the protective effects are augmented and the negative effects dampened.
