Alzheimer's disease causes a progressive dementia that currently affects over 35 million individuals worldwide and is expected to affect 115 million by 2050 (ref. 1). There are no cures or disease-modifying therapies, and this may be due to our inability to detect the disease before it has progressed to produce evident memory loss and functional decline. Biomarkers of preclinical disease will be critical to the development of disease-modifying or even preventative therapies². Unfortunately, current biomarkers for early disease, including cerebrospinal fluid tau and amyloid- β levels³, structural and functional magnetic resonance imaging⁴ and the recent use of brain amyloid imaging⁵ or inflammaging⁶, are limited because they are either invasive, time-consuming or expensive. Blood-based biomarkers may be a more attractive option, but none can currently detect preclinical Alzheimer's disease with the required sensitivity and specificity⁷. Herein, we describe our lipidomic approach to detecting preclinical Alzheimer's disease in a group of cognitively normal older adults. We discovered and validated a set of ten lipids from peripheral blood that predicted phenoconversion to either amnesic mild cognitive impairment or Alzheimer's disease within a 2–3 year timeframe with over 90% accuracy. This biomarker panel, reflecting cell membrane integrity, may be sensitive to early neurodegeneration of preclinical Alzheimer's disease.

We enrolled 525 community-dwelling participants, aged 70 and older and otherwise healthy, into this 5-year observational study. Over the course of the study, 74 participants met criteria for amnesic mild cognitive impairment (aMCI) or mild Alzheimer's disease (AD)

(Online Methods); 46 were incidental cases at entry, and 28 phenoconverted (Converters) from nonimpaired memory status at entry (Converter_{pre}). The average time for phenoconversion to either aMCI or AD was 2.1 years (range 1–5 years). We defined three main participant groups in this paper: aMCI/AD, Converter and Normal Control (NC). The participants with aMCI and mild AD were combined into a single group (aMCI/AD) because this group was defined by a primary memory impairment, and aMCI is generally thought to reflect the earliest clinically detectable stage of AD. The aMCI/AD group included the Converters after phenoconversion. The Converters were included at two time points, prior to phenoconversion (Converter_{pre}), when memory was not impaired, and after phenoconversion (Converter_{post}), when memory was impaired and they met criteria for either aMCI or AD. The NC group was selected to match the whole aMCI/AD group on the basis of age, education and sex. In the third year of the study, we selected 53 participants with either aMCI or AD for metabolomic and lipidomic biomarker discovery. Included in this aMCI/AD group were 18 Converters. We also selected 53 matched cognitively normal control (NC) participants. For the Converters, blood from both time 0 (at entry to the study) and after phenoconversion was used; for the other subjects, blood from the last available visit was used. We used an internal cross-validation procedure to evaluate the accuracy of the discovered lipidomics profile in classifying 41 additional subjects, consisting of the remaining subset of 21 participants with aMCI/AD, including 10 Converters, and 20 matched NC participants (Supplementary Table 1 and Supplementary Fig. 1).

The aMCI/AD, Converter and NC groups were defined primarily using a composite measure of memory performance (the decline in Z_{mem} for the Converters (C_{pre} versus C_{post}) is shown Fig. 1a). In addition,

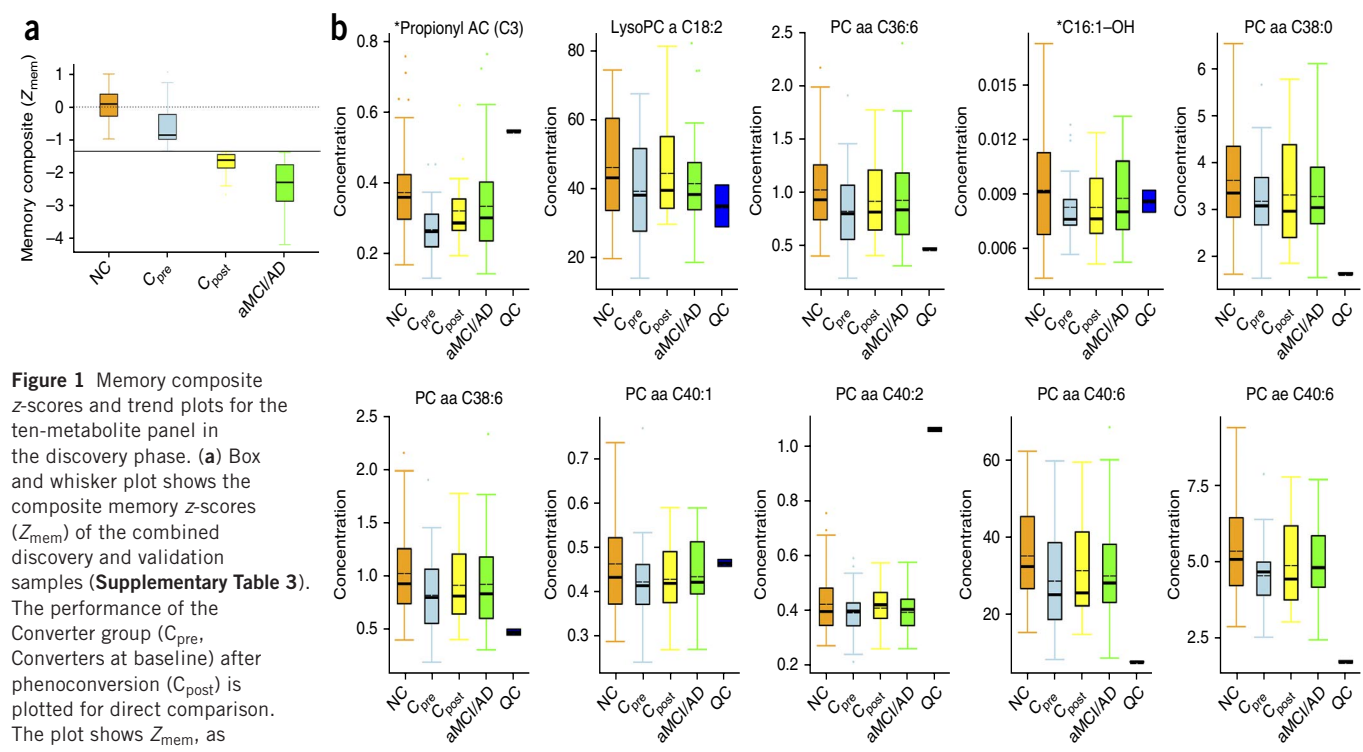

Figure 1 Memory composite z-scores and trend plots for the ten-metabolite panel in the discovery phase. (a) Box and whisker plot shows the composite memory z-scores (Z_{mem}) of the combined discovery and validation samples (Supplementary Table 3). The performance of the Converter group (C_{pre} , Converters at baseline) after phenoconversion (C_{post}) is plotted for direct comparison. The plot shows Z_{mem} , as described in Supplementary Table 3. The dotted line centered on 0 represents the median memory composite z-score for the entire cohort of 525 participants, and the black horizontal line represents the cut-off for impairment (-1.35 s.d.). Error bars represent \pm s.e.m. As defined, all converters had nonimpaired memory at baseline and impaired memory after phenoconversion. NC, $n = 73$; C_{pre} , $n = 28$; C_{post} , $n = 28$; and aMCI/AD, $n = 46$. (b) The SID-MRM-MS-based quantitative profiling data was subjected to the nonparametric Kruskal-Wallis test using the STAT pack module (Biocrates). Results are shown for a panel of ten metabolites in the NC group ($n = 53$), C_{pre} ($n = 18$), C_{post} ($n = 18$) and aMCI/AD ($n = 35$) groups, respectively. The abundance of each metabolite is plotted as normalized concentrations units (nM). The black solid bars within the boxplot represent the median abundance, and the dotted line represents mean abundance for the given group. Error bars represent \pm s.d. QC, quality control samples. The P values for analytes between groups were $P \leq 0.05$. The two metabolites with P values <0.005 are indicated with an asterisk. Each Kruskal-Wallis test was followed by Mann-Whitney U -tests for *post hoc* pairwise comparisons (NC versus C_{pre} and NC versus aMCI/AD). Significance was adjusted for multiple comparisons using Bonferroni's method ($P < 0.025$).

composite measures of other cognitive abilities (Supplementary Fig. 2) and measures of memory complaints and functional capacities were compiled (Supplementary Tables 2 and 3). The discovery and validation groups did not differ on clinical measures ($F(4,170) = 1.376$, $P = 0.244$) or on any composite z-score ($F(5,169) = 2.118$, $P = 0.066$), demonstrating the general equivalence of the participants used for the discovery and validation phases of the biomarker analysis.

We examined 124 plasma samples from the 106 discovery-phase participants for untargeted metabolomic analysis (Online Methods). Metabolomic and lipidomic profiling yielded 2,700 positive-mode features and 1,900 negative-mode features. Metabolites defining the participant groups were selected using the least absolute shrinkage and selection operator (LASSO) penalty^{8,9}. The LASSO analysis revealed features that assisted in unambiguous class separation between the two non-impaired groups, the Converter_{pre} group and the NC subjects who do not phenoconvert (Table 1). This untargeted analysis revealed considerably lower phosphatidylinositol in the Converter_{pre} group and higher glycourso-deoxycholic acid in the aMCI/AD group compared to the NC group. These metabolites were unambiguously identified using tandem mass spectrometry (Supplementary Fig. 3).

The untargeted LASSO analysis revealed amino acids and phospholipids to be potent discriminators of the NC and aMCI/AD groups. Thus, we performed stable isotope dilution–multiple reaction monitoring (MRM) mass spectrometry (SID-MRM-MS) to unambiguously identify and quantify lipids, amino acids and biogenic amines; this would discriminate our groups with emphasis on differences that might predict phenoconversion from NC to aMCI/AD. This targeted analysis revealed significantly lower plasma levels of serotonin, phenylalanine, proline, lysine, phosphatidylcholine (PC), taurine and acylcarnitine (AC) in Converter_{pre} participants who later phenoconverted to aMCI/AD (Table 2).

A notable finding of this targeted metabolomic and lipidomic analysis was the identification of a set of ten metabolites, comprising PCs, (PC diacyl (aa) C36:6, PC aa C38:0, PC aa C38:6, PC aa C40:1, PC aa

Table 1 Putative metabolite markers resulting from binary comparison of the study groups

Metabolite	LASSO coefficient	Comparison groups	Mode	Mass/charge ratio
Phosphatidylinositol (18:0/0:0)	↓ (−0.674)	NC versus Converter _{pre}	NEG	599.3226
Proline-asparagine dipeptide	↑ (0.192)	NC versus aMCI/AD	POS	230.1146
Glycourso-deoxycholic acid	↑ (0.107)	NC versus aMCI/AD	POS	450.3196
Malic acid	↓ (−0.024)	NC versus aMCI/AD	POS	134.0207

The markers were chosen on the basis of significant predictive value as determined by LASSO coefficient analysis. The positive estimated LASSO coefficient suggests elevation in corresponding comparison group (aMCI/AD and Converter_{pre}) compared to NC participants. Arrows indicate upregulation or downregulation in the comparison group as compared to the NC participants. NEG, negative; POS, positive.

C40:2, PC aa C40:6, PC acyl-alkyl (ae) C40:6), lysophosphatidylcholine (lysoPC a C18:2), and acylcarnitines (ACs) (Propionyl AC (C3) and C16:1-OH) that were depleted in the plasma of the Converter_{pre} participants but not in that of the NC group (Fig. 1b). These metabolites remained depleted after phenoconversion to aMCI/AD (Converters_{post}) and were similar to the levels in the aMCI/AD group.

We then performed targeted quantitative metabolomic and lipidomic analyses using plasma from a separate group of 40 participants as an independent blinded cross-validation, as one sample from the aMCI/AD group was not available for lipidomic analysis. The validation samples were obtained from those clinically defined NC, Converter_{pre}, aMCI/AD subjects. The samples were processed and analyzed using the same SID-MRM-MS technique as in the discovery phase. The targeted quantitative analysis of the validation set revealed similar levels for the ten-metabolite panel (Supplementary Fig. 4) as were observed in the discovery samples (Fig. 1b).

We used the metabolomic data from the untargeted LASSO analysis to build separate linear classifier models that would distinguish the aMCI/AD and Converter_{pre} groups from the NC group. We used receiver operating characteristic (ROC) analysis to assess the performance of the classifier models for group classification. For the Converter_{pre} and NC group classification, the initial LASSO-identified metabolites yielded a robust area under the curve (AUC) of 0.96 (Fig. 2a) and a more modest AUC of 0.83 for aMCI/AD and NC group classification. A separate classifier model using the discovered ten-metabolite panel from the targeted metabolomic analysis classified Converter_{pre} and NC participants with an AUC of 0.96 (Fig. 2b) and an AUC of 0.827 for the aMCI/AD versus NC classification. To validate our biomarker-based group classification, we applied the same simple logistic classifier model developed for the discovery samples to the independent validation samples. The model classified Converter_{pre} and NC participants with an AUC of 0.92 (Fig. 2c) and an AUC of 0.77 for the aMCI/AD versus NC groups. This model yielded a sensitivity of 90% and specificity of 90%, for classifying the Converter_{pre} and NC groups in the validation phase (Fig. 2c).

We then considered the effects of apolipoprotein E (APOE) genotype on our classification of the Converter_{pre} and NC groups. APOE is involved in lipid metabolism, with the $\epsilon 4$ allele known to be a risk factor for AD. The proportion of $\epsilon 4$ allele carriers was similar in the aMCI/AD (19/69 = 27.5%), NC (17/73 = 23%) and Converter (5/28 = 17%) groups ($\chi^2 = 0.19$, $P = 0.68$, not significant). We repeated the classification analyses using the ten-metabolite model with APO

Table 2 Difference detection of putative metabolites using SID-MRM-MS

Metabolite	Fold change	Comparison groups	Mode	P value
PC ae C38:4	↓	NC versus Converter _{pre}	POS	0.00417
Proline	↓	NC versus Converter _{pre}	POS	0.00003
Lysine	↓	NC versus Converter _{pre}	POS	0.0020
Serotonin	↓	NC versus Converter _{pre}	POS	0.0160
Taurine	↓	NC versus Converter _{pre}	POS	0.0030
DOPA	↑	NC versus Converter _{pre}	POS	0.0001
Phenylalanine	↓	NC versus Converter _{pre}	POS	0.00001
Acylcarnitine C7-DC	↓	NC versus aMCI/AD	POS	0.0001

The arrows indicate upregulation or downregulation in the comparison group as compared to the NC participants. DOPA, dihydroxyphenylalanine; C7-DC, pimelyl-L-carnitine.

$\epsilon 4$ allele as a covariate. The effect of the $\epsilon 4$ allele was not significant ($P = 0.817$), and classification accuracy for Converter_{pre} and NC groups changed minimally from an AUC 0.96 to 0.968 ($P = 0.992$, not significant). Furthermore, a classifier model using only APOE $\epsilon 4$ produced an AUC of 0.54 for classifying the Converter_{pre} and NC groups, implying virtually random classification. These findings indicate that the presumed pathophysiology reflected by the ten-metabolite biomarker panel is orthogonal to APOE-mediated effects.

Here we present the discovery and validation of plasma metabolite changes that distinguish cognitively normal participants who will progress to have either aMCI or AD within 2–3 years from those destined to remain cognitively normal in the near future. The defined ten-metabolite profile features PCs and ACs, phospholipids that have essential structural and functional roles in the integrity and functionality of cell membranes^{10,11}. Deficits of the plasmalemma in AD have been described previously¹². Studies have shown decreased plasma PC levels¹³ and lysoPC/PC ratios¹⁴ and increased cerebrospinal fluid (CSF) PC metabolites in patients with AD¹⁵, as well as decreased phosphatidylinositol in the hippocampus¹⁶ and other heteromodal cortical regions¹⁷. Furthermore, amyloid- β may directly disrupt bilayer integrity by interacting with phospholipids¹⁸. ACs are known to have a major role in central carbon and lipid metabolism occurring within the mitochondria¹¹. They have also been associated with regulation, production and maintenance of neurons through enhancement of nerve growth factor production¹¹, which is a known potent survival and trophic factor for brain cholinergic neurons, particularly those consistently affected by AD within the basal forebrain^{19–21}. Decreasing plasma AC levels in the Converter_{pre} participants in our study may indirectly signal an impending dementia cascade that features loss of these cholinergic neuronal populations. We posit that this ten-phospholipid biomarker panel, consisting of PC and AC species, reveals the breakdown of neural cell membranes in those individuals destined to phenoconvert from cognitive intactness to

Figure 2 ROC results for the lipidomics analyses. (a–c) Plots of ROC results from the models derived from the three phases of the lipidomics analysis. Simple logistic models using only the metabolites identified in each phase of the lipidomics analysis were developed and applied to determine the success of the models for classifying the C_{pre} and NC groups. The red line in each plot represents the AUC obtained from the discovery-phase LASSO analysis (a), the targeted analysis of the ten metabolites in the discovery phase (b) and the application of the ten-metabolite panel developed from the targeted discovery phase in the independent validation phase (c). The ROC plots represent sensitivity (i.e., true positive rate) versus 1 – specificity (i.e., false positive rate).

aMCI or AD and may mark the transition between preclinical states where synaptic dysfunction and early neurodegeneration give rise to subtle cognitive changes².

Most approaches to fluid-based biomarker discovery have focused on amyloid- β_{1-42} (A β 42), total tau and phosphorylated tau-181 obtained from CSF. Classification of symptomatic patients versus normal controls or other dementias or conversion from MCI to AD is high²², but the predictive value of these CSF biomarkers in pre-clinical patients is not as strong, suggesting that these markers may be useful only for confirmation of clinical diagnosis²³. Blood-based biomarkers are not routinely used in clinical practice but may be more useful because they are easily obtained with less risk of complication in older adults. Studies focusing on A β 42 or A β 42/tau ratios derived from blood have been disappointing²⁴, but recent studies suggest that assessment of the proteome and metabolome in blood may have more promise. One recent study using plasma identified 18 proteins that discriminated subjects with symptomatic AD from normal control subjects with nearly 90% accuracy and predicted conversion from symptomatic MCI to AD with 91% accuracy²⁵. Another cross-sectional study reported 18 plasma biomarkers, many related to inflammation, that correctly classified subjects with symptomatic AD and normal control subjects with a sensitivity and specificity of 85% and an AUC of 93% (ref. 26). The biomarker panel was externally validated in a cohort of normal control subjects and subjects with symptomatic AD with sensitivity and specificity of 80% and an AUC of 85%.

To our knowledge, this is the first published report of a blood-based biomarker panel with very high accuracy for detecting preclinical AD. This metabolic panel robustly identifies (with accuracy above 90%) cognitively normal individuals who, on average, will phenocopy to aMCI or AD within 2–3 years. The accuracy for detection is equal to or greater than that obtained from most published CSF studies^{27,28}, and blood is easier to obtain and costs less to acquire, making it more useful for screening in large-scale clinical trials and for future clinical use. This biomarker panel requires external validation using similar rigorous clinical classification before further development for clinical use. Such additional validation should be considered in a more diverse demographic group than our initial cohort. We consider our results a major step toward the NIA-AA (National Institute on Aging and Alzheimer's Association) consensus statement mandate for biomarkers of preclinical AD².

ONLINE METHODS

Neurocognitive methods. The University of Rochester Research Subjects Review Board and the University of California, Irvine Institutional Review Board each approved a common research protocol for this investigation. Content of informed consent forms was thoroughly discussed with subjects at the time of entry into the study and verbal and written consent was obtained from all subjects, including that for serial neuropsychological testing and blood draws for biomarker evaluation. A total of 525 volunteers participated in this study as part of the Rochester/Orange County Aging Study, an ongoing natural history study of cognition in community-dwelling older adults (**Supplementary Note**). All participants were community-dwelling older adults from the greater Rochester, NY, and Irvine, CA, communities. Participants were recruited through local media (newspaper and television advertisements), senior organizations and word of mouth. Inclusion criteria included age 70 or older, proficiency with written and spoken English and corrected vision and hearing necessary to complete the cognitive battery. Participants were excluded for the presence of known major psychiatric or neurological illness (including Alzheimer's disease or MCI, cortical stroke, epilepsy and psychosis) at time of enrollment, current or recent (<1 month) use of anticonvulsants, neuroleptics, HAART, antiemetics and antipsychotics for any reason and serious blood diseases including chronic abnormalities in complete blood count and anemia requiring therapy and/or transfusion. Briefly, we prospectively followed participants with yearly cognitive assessments and collected blood samples following an overnight fast (withholding of all medications) (**Supplementary Note**). At enrollment, each participant completed detailed personal, medical and family history questionnaires. At baseline and at each yearly visit, participants completed measures assessing activities of daily living, memory complaints, and signs and symptoms of depression and were given a detailed cognitive assessment (**Supplementary Table 2**).

For this study, data from the cognitive tests were used to classify our participants into groups for biomarker discovery. We derived standardized scores (*z*-scores) for each participant on each cognitive test and computed composite *z*-scores for five cognitive domains (attention, executive, language, memory and visuo-perceptual) (**Supplementary Table 3**). Normative data for *z*-score calculations were derived from the performance of our participants on each of the cognitive tests adjusted for age, education, sex and visit. To reduce the effect of cognitively impaired participants on the mean and s.d., age-, education-, sex- and visit-adjusted residuals from each domain *z*-score model were robustly standardized to have median 0 and robust s.d. of 1, where the robust s.d. = IQR/1.35, as 1.35 is the IQR (interquartile range) of a standard normal distribution.

We categorized the participants into groups of subjects with incident aMCI or early AD (combined into one category, aMCI/AD), cognitively NC subjects and those who converted to aMCI or AD over the course of the study (Converters) based on these composite scores. Impairment was defined as a *z*-score 1.35 below the cohort median. All participants classified as aMCI met recently revised criteria²⁹ for the amnesic subtype of MCI³⁰. We excluded other behavioral phenotypes of MCI in order to concentrate on the amnesic, which most likely represents nascent AD pathology³¹. All participants with early AD met recently revised criteria for probable AD³² with impairment in memory and at least one other cognitive domain. For the aMCI/AD group, scores on the measures of memory complaints (MMQ) and activities of daily living (PGC-IADL) were used to corroborate research definitions of these states. All Converters had nonimpaired memory at entry to the study ($Z_{\text{mem}} \geq -1.35$), developed memory impairment over the course of the study ($Z_{\text{mem}} \leq -1.35$) and met criteria for the above definitions of aMCI or AD. To enhance the specificity of our biomarker analyses, NC participants in this study were conservatively defined with $Z_{\text{mem}} \pm 1$ s.d. of the cohort median rather than simply ≥ -1.35 , and all other *z*-scores ≥ -1.35 s.d. (**Supplementary Note**).

At the end of year 3 of the study, 202 participants had completed a baseline and two yearly visits. At the third visit, 53 participants met criteria for aMCI/AD and 96 met criteria for NC. Of the 53 aMCI/AD participants, 18 were Converters and 35 had incident aMCI or AD. The remaining 53 participants did not meet our criteria for either group and were not considered for biomarker profiling. Some of these individuals met criteria for nonamnesic MCI, and many had borderline or even above average memory scores that precluded their inclusion as either aMCI/AD or NC (**Supplementary Fig. 1**). We matched 53 NC

participants to the 53 aMCI/AD participants based on sex, age and education level. We used blood samples obtained on the last available study visit for the 53 MCI/AD and 53 NC for biomarker discovery. We included two blood samples from each of the 18 Converters, one from the baseline visit (Converter_{pre}) when Z_{mem} was nonimpaired and one from the third visit (Converter_{post}) when Z_{mem} was impaired and they met criteria for either aMCI or AD. Thus, a total of 124 samples from 106 participants were submitted for biomarker discovery.

We employed internal cross-validation to validate findings from the discovery phase. Blood samples for validation were identified at the end of the fifth year of the study, and all 106 participants included in the discovery phase were excluded from consideration for the validation phase (**Supplementary Fig. 1**). Cognitive composite *z*-scores were recalculated based on the entire sample available, and the same procedure and criteria were used to identify samples for the validation phase. A total of 145 participants met criteria for a group: 21 aMCI/AD and 124 NC. Of the 21 aMCI/AD, 10 were Converters. We matched 20 NC participants to the aMCI/AD participants on the basis of age, sex and education level as in the discovery phase. In total, 40 participants contributed plasma samples to the validation phase, as 1 aMCI/AD subject's plasma sample was not able to be used. As before, the 10 Converters also contributed a baseline sample (Converter_{pre}) for a total of 50 samples.

Neurocognitive statistical analyses. The neurocognitive analyses were designed to demonstrate the general equivalence of the discovery and validation samples on clinical and cognitive measures. We used separate multivariate ANOVA (MANOVA) to examine discovery and validation group performance on the composite *z*-scores and on self-reported measures of memory complaints, memory related functional impairment and depressive symptoms, as well as a global measure of cognitive function. In the first MANOVA, biomarker sample (discovery, validation) was the independent variable and MMQ, IADL, geriatric depression scale and mini-mental state examination were the dependent variables. In the second MANOVA, biomarker sample (discovery, validation) was the independent variable, and the five cognitive domain *z*-scores (Z_{att} , Z_{exe} , Z_{lan} , Z_{mem} and Z_{vis}) were the dependent variables. Significance for the two-sided tests was set at $\alpha = 0.05$, and we used Tukey's honestly significant difference (HSD) procedure for *post hoc* comparisons. All statistical analyses were performed using SPSS (version 21).

Lipidomics methods. Reagents. Liquid chromatography–mass spectrometry (LC-MS)–grade acetonitrile, isopropanol, water and methanol were purchased from Fisher Scientific (New Jersey, USA). High purity formic acid (99%) was purchased from Thermo-Scientific (Rockford, IL). Debrisoquine, 4-nitrobenzoic acid (4-NBA), Pro-Asn, glycocholateoxycholic acid and andolic acid were purchased from Sigma (St. Louis, MO, USA). All lipid standards including 14:0 LPA, 17:0 Ceramide, 12:0 LPC, 18:0 Lyso PI and PC(22:6/0:0) were procured from Avanti Polar Lipids (USA).

Metabolite extraction. Briefly, the plasma samples were thawed on ice and vortexed. For metabolite extraction, 25 μL of plasma sample was mixed with 175 μL of extraction buffer (25% acetonitrile in 40% methanol and 35% water) containing internal standards (10 μL of debrisoquine (1 mg/mL), 50 μL of 4, nitrobenzoic acid (1 mg/mL), 27.3 μL of ceramide (1 mg/mL) and 2.5 μL of LPA (lysophosphatidic acid) (4 mg/mL) in 10 mL). The samples were incubated on ice for 10 min and centrifuged at 14,000 r.p.m. at 4 °C for 20 min. The supernatant was transferred to a fresh tube and dried under vacuum. The dried samples were reconstituted in 200 μL of buffer containing 5% methanol, 1% acetonitrile and 94% water. The samples were centrifuged at 13,000 r.p.m. for 20 min at 4 °C to remove fine particulates. The supernatant was transferred to a glass vial for Ultraperformance liquid chromatography–electrospray ionization quadrupole time-of-flight mass spectrometry (UPLC-ESI-QTOF-MS) analysis.

UPLC-ESI-QTOF-MS-based data acquisition for untargeted lipidomic profiling. Each sample (2 μL) was injected onto a reverse-phase CSH C18 1.7 μM 2.1x100 mm column using an Acquity H-class UPLC system (Waters Corporation, USA). The gradient mobile phase comprised of water containing 0.1% formic acid solution (Solvent A), 100% acetonitrile (Solvent B) and 10% acetonitrile in isopropanol containing 0.1% formic acid and 10 mM ammonium formate (Solvent C). Each sample was resolved for 13 min at a flow rate of 0.5 mL/min for 8 min and then 0.4 mL/min from 8 to 13 min.

The UPLC gradient consisted of 98% A and 2% B for 0.5 min and then a ramp of curve 6 to 60% B and 40% A from 0.5 min to 4.0 min, followed by a ramp of curve 6 to 98% B and 2% A from 4.0 to 8.0 min, a ramp to 5% B and 95% C from 9.0 min to 10.0 min at a flow rate of 0.4 mL/min and finally a ramp to 98% A and 2% B from 11.0 min to 13 min. The column eluent was introduced directly into the mass spectrometer by electrospray ionization. Mass spectrometry was performed on a quadrupole time-of-flight (Q-TOF) instrument (Xevo G2 QTOF, Waters Corporation, USA) operating in either negative (ESI⁻) or positive (ESI⁺) electrospray ionization mode with a capillary voltage of 3,200 V in positive mode and 2,800 V in negative mode and a sampling cone voltage of 30 V in both modes. The desolvation gas flow was set to 750 L h⁻¹, and the temperature was set to 350 °C. The source temperature was set at 120 °C. Accurate mass was maintained by introduction of a lock-spray interface of leucine-enkephalin (556.2771 [M+H]⁺ or 554.2615 [M-H]⁻) at a concentration of 2 pg/μL in 50% aqueous acetonitrile and a rate of 2 μL/min. Data were acquired in centroid MS mode from 50 to 1,200 *m/z* mass range for TOF-MS scanning as single injection per sample, and the batch acquisition was repeated to check experimental reproducibility. For the metabolomics profiling experiments, pooled quality control (QC) samples (generated by taking an equal aliquot of all the samples included in the experiment) were run at the beginning of the sample queue for column conditioning and every ten injections thereafter to assess inconsistencies that are particularly evident in large batch acquisitions in terms of retention time drifts and variation in ion intensity over time. This approach has been recommended and used as a standard practice by leading metabolomics researchers³³. A test mix of standard metabolites was run at the beginning and at the end of the run to evaluate instrument performance with respect to sensitivity and mass accuracy. The overlay of the total ion chromatograms of the quality control samples depicted excellent retention time reproducibility. The sample queue was randomized to remove bias.

Stable isotope dilution–multiple reaction monitoring mass spectrometry. LC-MS/MS mass spectrometry (LC-MS/MS) is increasingly used in clinical settings for quantitative assay of small molecules and peptides such as vitamin D, serum bile acid and parathyroid hormone under Clinical Laboratory Improvement Amendments environments with high sensitivities and specificities³⁴. In this study, targeted metabolomic analysis of plasma samples was performed using the Biocrates Absolute-IDQ P180 (BIOCRATES, Life Science AG, Innsbruck, Austria). This validated targeted assay allows for simultaneous detection and quantification of metabolites in plasma samples (10 μL) in a high-throughput manner. The methods have been described in detail^{35,36}. The plasma samples were processed as per the instructions by the manufacturer and analyzed on a triple-quadrupole mass spectrometer (Xevo TQ-S, Waters Corporation, USA) operating in the MRM mode. The measurements were made in a 96-well format for a total of 148 samples, and seven calibration standards and three quality control samples were integrated in the kit. Briefly, the flow injection analysis tandem mass spectrometry (MS/MS) method was used to quantify a panel of 144 lipids simultaneously by multiple reaction monitoring. The other metabolites are resolved on the UPLC and quantified using scheduled MRMs. The kit facilitates absolute quantitation of 21 amino acids, hexose, carnitine, 39 acylcarnitines, 15 sphingomyelins, 90 phosphatidylcholines and 19 biogenic amines. Data analysis was performed using the MetIQ software (Biocrates), and the statistical analyses included the nonparametric Kruskal-Wallis test with follow-up Mann-Whitney *U*-tests for pairwise comparisons using the STAT pack module v3 (Biocrates). Significance was adjusted for multiple comparisons using Bonferroni's method (*P* < 0.025). The abundance is calculated from area under the curve by normalizing to the respective isotope labeled internal standard. The concentration is expressed as nmol/L. Human EDTA plasma samples spiked with standard metabolites were used as quality control samples to assess reproducibility of the assay. The mean of the coefficient of

variation (CV) for the 180 metabolites was 0.08, and 95% of the metabolites had a CV of <0.15.

Sample size considerations. The signal intensity of the metabolites within similar groups was normally distributed with a standard deviation of 1.5. If the true difference in the Converterpre and NC groups' mean is twofold, we will have over 90% power to detect differential metabolites at an overall significance level of 5% with Bonferroni's adjustment using 30 subjects per group.

Lipidomics statistical analyses. The *m/z* features of metabolites were normalized with log transformation that stabilized the variance, followed by a quantile normalization to make the empirical distribution of intensities the same across samples³⁷. The metabolites were selected among all those known to be identifiable using a ROC regularized learning technique^{38,39} based on the LASSO penalty^{8,9} as implemented with the R package 'glmnet'⁴⁰, which uses cyclical coordinate descent in a path-wise fashion. We first obtained the regularization path over a grid of values for the tuning parameter λ through tenfold cross-validation. The optimal value of the tuning parameter lambda, which was obtained by the cross-validation procedure, was then used to fit the model. All the features with nonzero coefficients were retained for subsequent analysis. This technique is known to reduce overfitting and achieve similar prediction accuracy as the sparse supporting vector machine. The classification performance of the selected metabolites was assessed using area under the ROC curve (AUC). The ROC can be understood as a plot of the probability of classifying correctly the positive samples against the rate of incorrectly classifying true negative samples. So the AUC measure of an ROC plot is a measure of predictive accuracy. To maintain rigor of independent validation, the simple logistic model with the ten-metabolite panel was used, although a more refined model can yield greater AUC. The validation phase was performed in a blinded fashion such that the sample group was not known by the statistical team.

Supplementary Figure 1a. Study flow diagram. This figure shows the number of participants available for biomarker profiling at each phase of the study. The Discovery phase participants were selected in year 3 of the study and included only the 202 participants with three consecutive visits **(a)**. The 53 participants who did not meet criteria for aMCI, AD, or NC were classified No Group and not used in the analysis. The Validation selection took place at the end of year 5 of the study **(b)**. Here, all participants whose plasma was profiled in the Discovery phase were excluded from consideration. 295 participants with at least three consecutive visits were available for selection. For both Discovery and Validation phases, the cognitive data and blood sample from the last available visit was used. Due to rolling enrollment and drop outs during the course of the study the number of completed participants do not sum to the number of participants available.

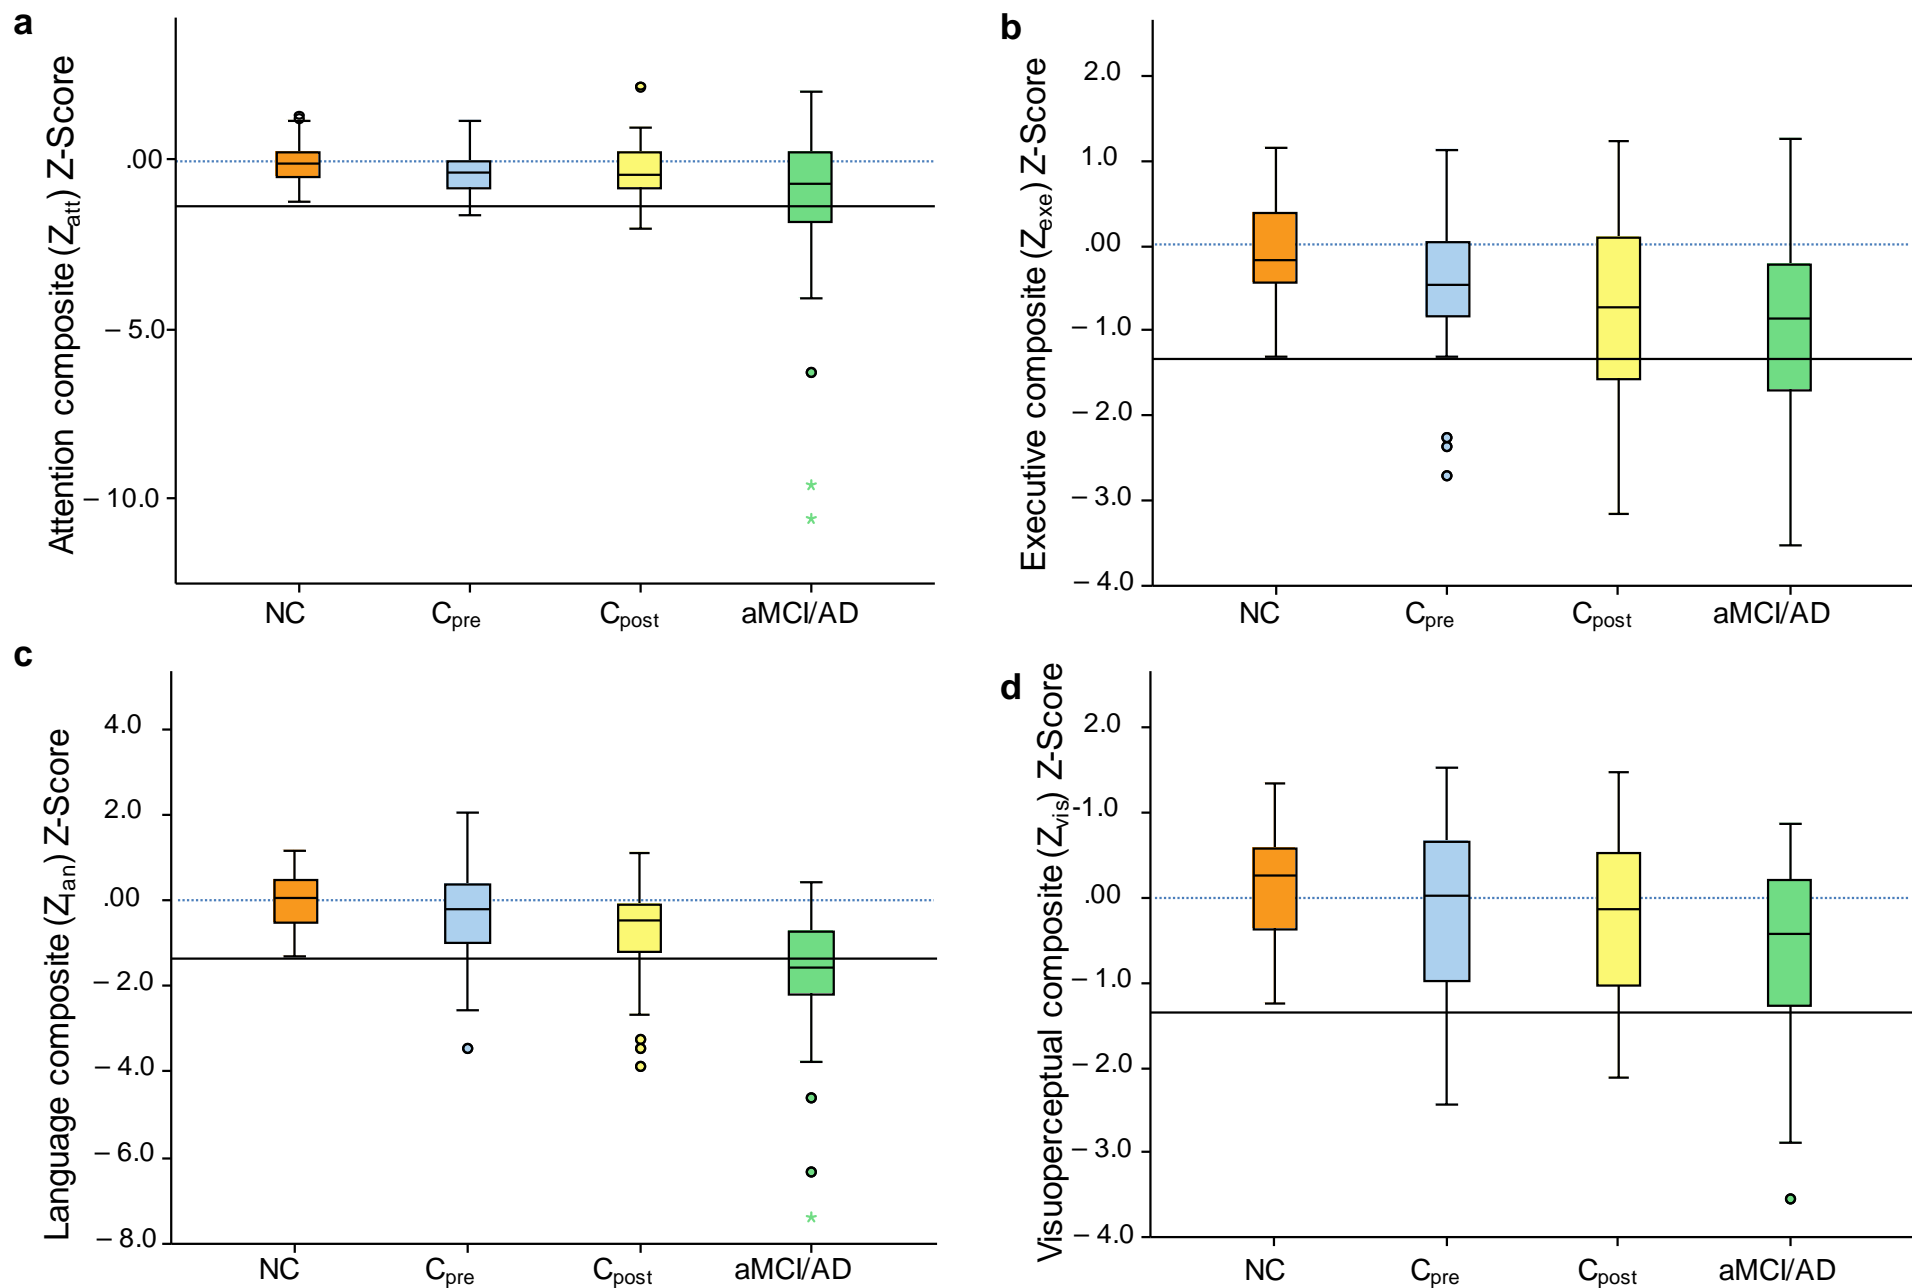

Discovery Phase

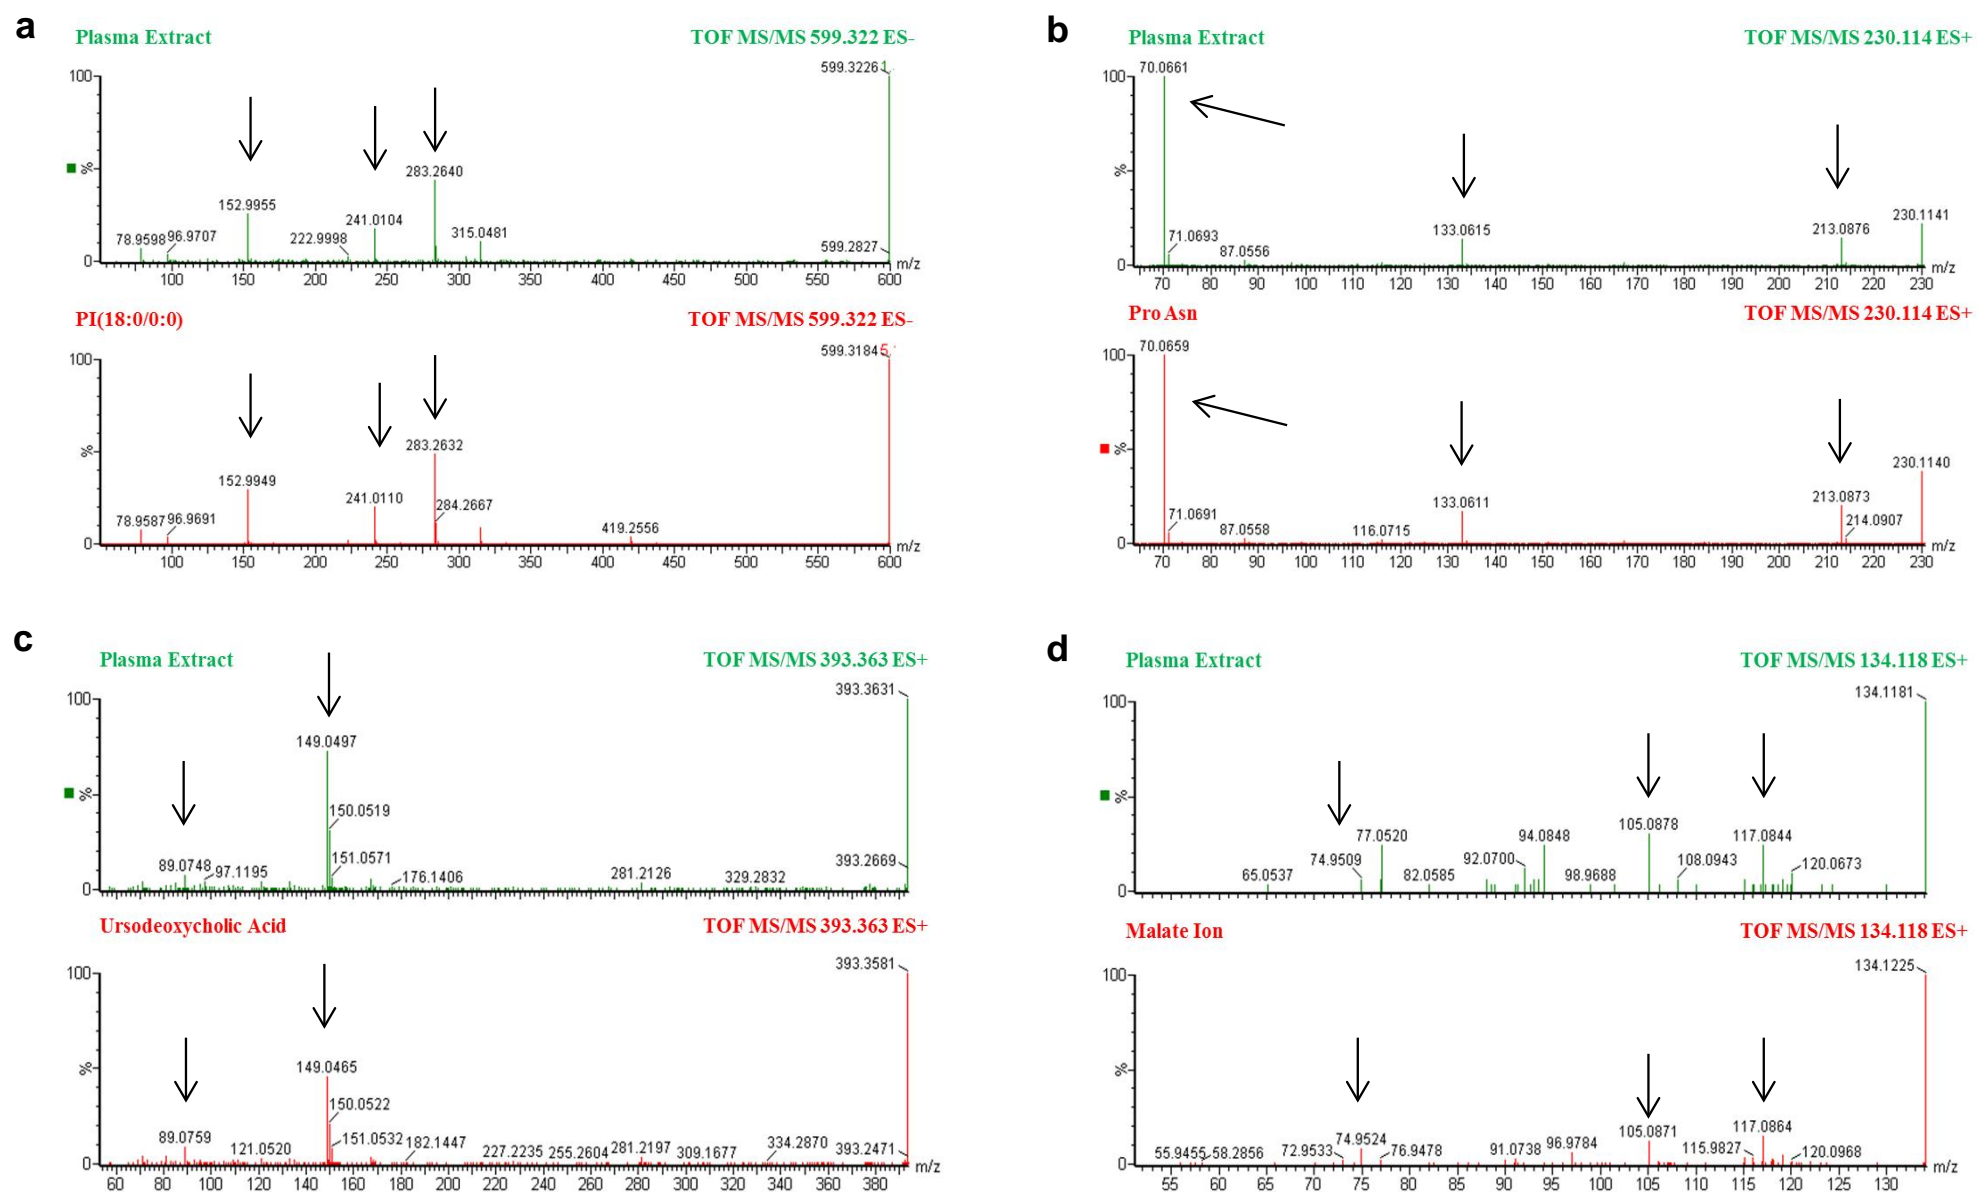

Validation Phase

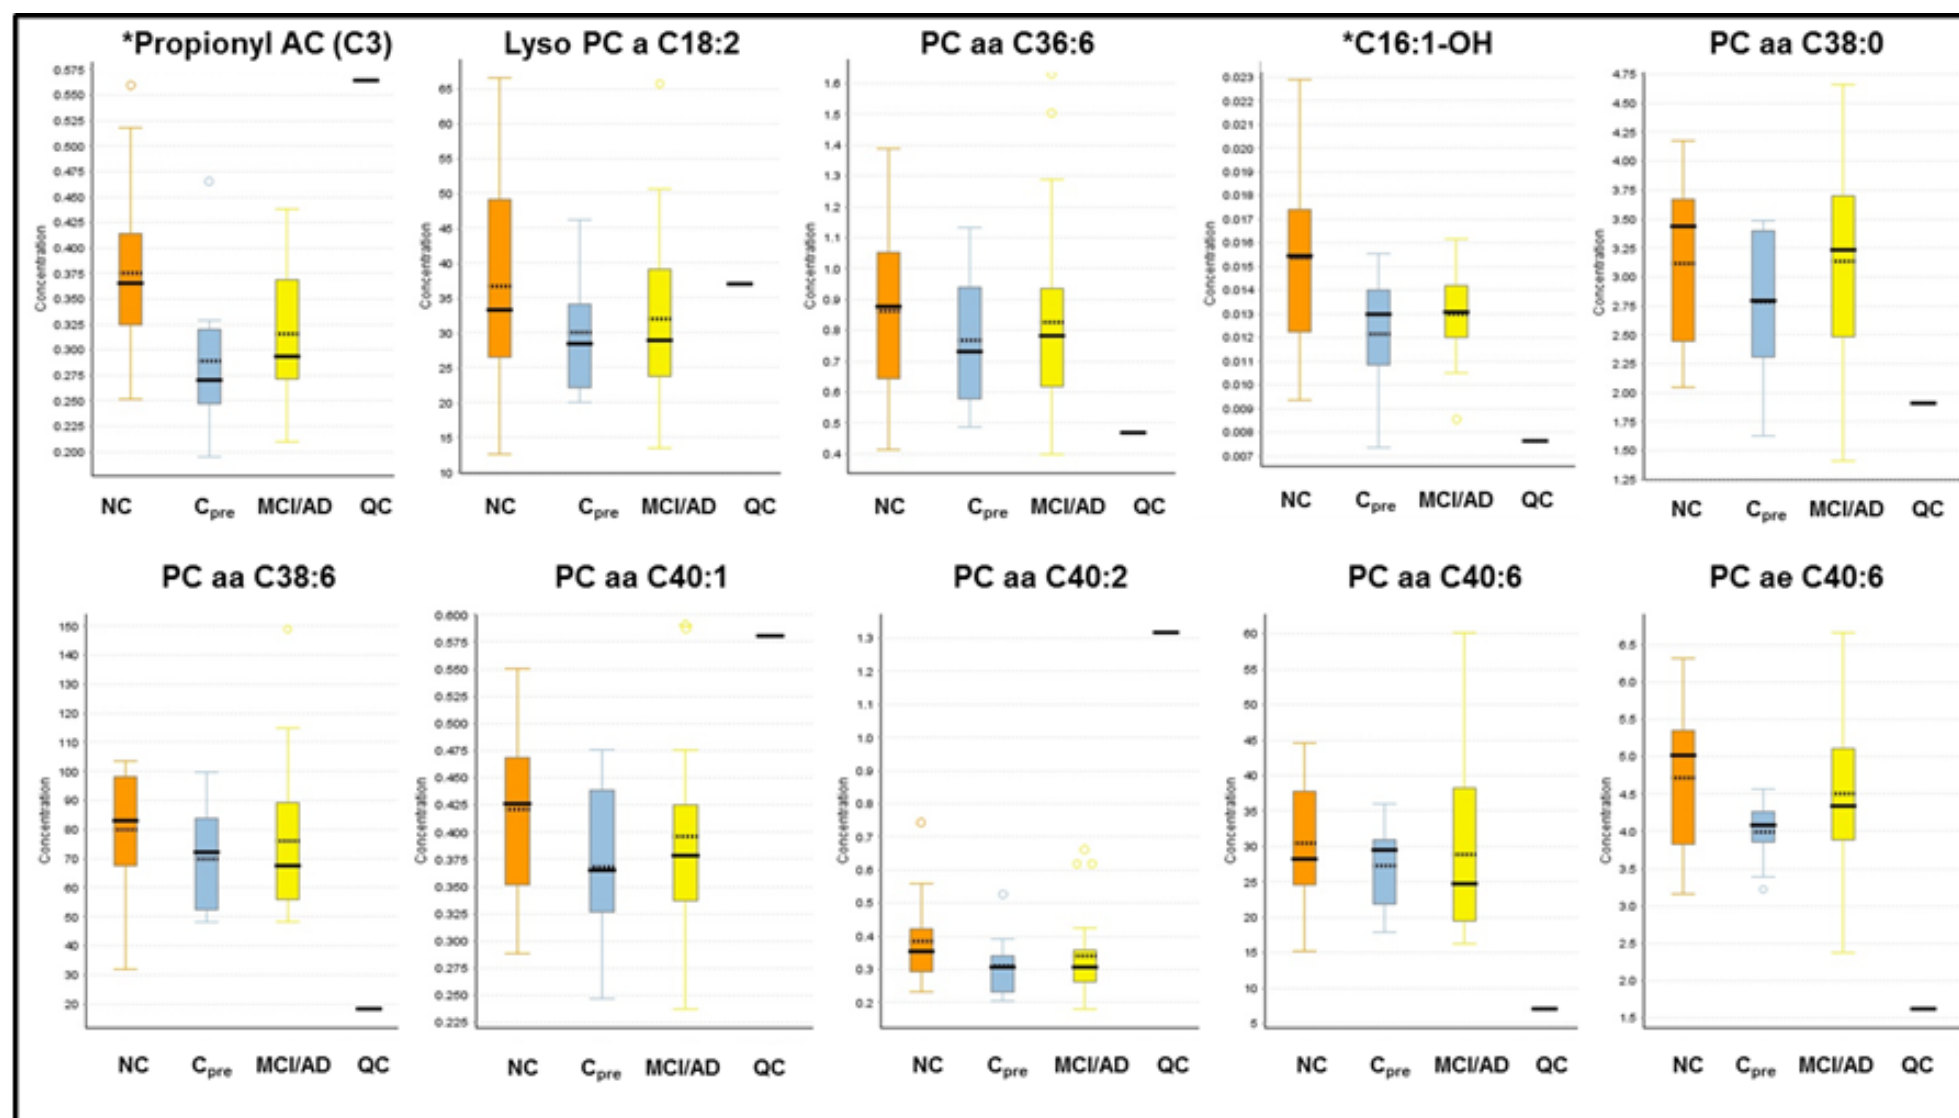

Supplementary Figure 1b. Composition of participant groups. This figure shows the composition of the participant groups used in the Discovery and Validation phases of the study. The Discovery phase included 106 participants in two age-, sex-, and education-matched groups of 53 individuals. The 53 aMCI/AD participants consisted of 35 incident cases and 18 who phenoconverted from a non-impaired memory state at entry to the study. The smaller Validation Phase included 41 participants in two age-, sex-, and education-matched groups of 20 normal controls and 21 aMCI/AD individuals. The 21 aMCI/AD consisted of 11 incident cases and 10 who phenoconverted.

Supplementary Figure 2. Cognitive composite Z-Scores for non-mnemonic domains. These box and whisker plots depict the composite Z-scores of the combined discovery and validation samples for the (a) Attention (Z_{att}), (b) Executive (Z_{exe}), (c) Language (Z_{lan}), and (d) Visuo-perceptual (Z_{vis}) domains. The performance of the Converter group after phenoconversion (C_{post}) is plotted for comparison. The blue line centered on 0 represents the median memory composite Z-score for the entire cohort of 525 participants. The black horizontal line represents the cut-off for impairment (-1.35 SD). Error bars represent s.e.m.

Supplementary Figure 3. Determination of chemical structures of metabolites in plasma extract by tandem mass spectrometry. The upper figure in each panel shows the unknown metabolite and lower panel shows the standard. Arrows indicate matching fragments in the metabolite and standard. **(a)** Metabolite with retention time 10.1 minutes and parent m/z of 599.32 identified as PI(18:0/0:0). **(b)** Metabolite with retention time of 2.5 minutes and parent m/z of 230.11 identified as Pro Asn. **(c)** Metabolite with retention time of 5.1 minutes and m/z of 393.363 identified as ursodeoxycholic acid. The glycine conjugate of ursodeoxycholic acid yields a parent m/z of 450 in the positive electrospray mode. **(d)** Metabolite with retention time of 0.6 minutes under the chromatographic conditions used and parent m/z of 134.118 in electrospray positive mode identified as Malate.

Supplementary Figure 4. Trend plots for the ten metabolite panel- Validation phase. This figure shows the results of the internal cross-validation for each of the ten metabolites using targeted quantitative mass spectrometry. The black solid and dotted lines in the boxplots represent median and mean abundance respectively, for the given group. The three groups depicted include NC (n=20), Converter_{pre} (n=10), and aMCI/AD (n=20). One of the aMCI/AD samples was not available for lipidomic analysis. The quantitative profiling data were subjected to the non-parametric Kruskal Wallis test using STAT pack module (Biocrates) for building a classifier based on differential abundance of metabolites in each group. Error bars are s.d. QC shows the scatter in the quality control samples. The p-values for analytes between groups were $p \leq 0.05$. The two metabolites with p-values less than 0.005 are indicated with an asterisk. Each Kruskal-Wallis test was followed by Mann-Whitney U Tests for post-hoc pair-wise comparisons (NC vs C_{pre} and NC vs aMCI/AD). Significance was adjusted for multiple comparisons using Bonferroni's method ($p < 0.025$). The NC group had significantly higher levels of C16:1-OH, C3, PC aa C36:6, PC aa C40:2, PC aa C40:6, and PC ae C40:6 compared to the C_{pre} group and also higher levels of C16:1-OH, C3, lysoPC a C18:2, PC aa C38:6 and PC aa C40:6 compared to the aMCI/AD group.

SUPPLEMENTARY NOTE

Participants

All participants were community-dwelling, older adults from the greater Rochester, NY and Irvine, CA communities. Participants were recruited through local media (newspaper and television advertisements), senior organizations, and word of mouth. Inclusion criteria included age 70 or older, proficiency with written and spoken English and corrected vision and hearing necessary to complete the cognitive battery. Participants were excluded for the presence of known major psychiatric or neurological illness (including Alzheimer's disease or MCI, cortical stroke, epilepsy, and psychosis) at time of enrollment, current or recent (< 1 month) use of anticonvulsants, neuroleptics, HAART, antiemetics, and antipsychotics for any reason, and serious blood diseases including chronic abnormalities in complete blood count and anemia requiring therapy and/or transfusion. All participants gave written informed consent and all procedures in this study were approved by the University of Rochester, University of California Irvine, and Georgetown University Research Studies Review Boards. Participant characteristics can be found in Supplemental Table 1.

Sample Size Considerations

The signal intensity of the metabolites within similar groups was normally distributed with standard deviation of 1.5. If the true difference in the Converter_{pre} and NC groups' mean is 2 fold, we will have over 90% power to detect differential metabolites at an overall significance level of 5% with Bonferroni's adjustment using 30 subjects per group.

Operationalizing groups for biomarker profiling

The primary Memory outcome was based on the Rey Auditory Visual Learning Test (RAVLT). *Learning* was defined as the sum of the number of correct words recalled over the 5 learning trials; *Retrieval* was defined as the total number of correct words recalled from trial A7; and *Retention* was defined as the total number correct words recognized minus the number of false positives. Each of these three sub-scores (Learning, Retrieval, and Retention) was converted to an empirical Z-score by subtracting its sample mean and dividing by its sample SD. The three resulting positively correlated RAVLT-based Z-scores were then averaged to form the composite *Memory* score (Z_{mem}). So defined, Z_{mem} was approximately normal with mean 0, $SD < 1$, and some negative skewness attributable to the fact that healthy participants often score at or near the upper bounds, especially for Retention.

The Attention (Z_{att}), Executive (Z_{exe}), and Language (Z_{lan}) scores were each defined as averages of empirical Z-score transforms of pairs of subscores, as follows. Z_{att} : (1) completion time (in seconds, truncated at 300s) for the Trail Making Test Part A and (2) the Wechsler Memory Scale-III Forward Digit Span; Z_{exe} : (1) completion time (in seconds, truncated at 300s) for the Trail Making Test Part B and (2) the Wechsler Memory Scale-III Backward Digit Span; Z_{lan} : (1) total score (out of 60) for the Boston Naming Test and (2) Category Fluency (Animals Named in 1 minute). The Visuospatial score (Z_{vis}) was simply the empirical Z-transform of the Total Score (out of 30) for the Hooper Visual Organization Test (HVOT), which itself was approximately normally distributed.

Standardization and Adjustment for Age, Gender, Education, and Visit

Linear Generalized Estimating Equation (GEE) models were used to model each of the five cognitive domains (Memory, Attention, Executive, Language, and Visuospatial) as a function of age, gender, education, and visit number, using a homoscedastic working independence covariance matrix. I.e., least squares was used to estimate all linear model coefficients based on the pooled data from all available visits at the Discovery phase and later at the Validation phase. Since Memory was the focal cognitive domain, the functional form for the covariates was selected to best model Memory, and exactly the same functional form was used for the other four cognitive domains. Given the evidence of nonlinearity, the effect of education was modeled using a continuous piecewise linear spline with knots at 12, 14, and 16 years of education. Memory increased with years of education between 5-12 years, decreased between 12-14 years, increased again between 14-16 years, and then nearly leveled off for 16-23 years. Age was modeled linearly, as there was insufficient evidence to support nonlinearity via piecewise linear spline knots or a quadratic component, yet Memory scores decreased linearly with age. Visit was modeled via an indicator for baseline visit 0, given that there was insufficient

evidence that subsequent visits differed from each other, yet there was evidence that subsequent visits had higher Memory scores compared with baseline visit 0. Gender was modeled via an indicator for males, who had lower memory scores than females. There was insufficient evidence to support any interactions. Residuals from each model were then robustly standardized to have median 0 and robust SD=1, where the robust SD = IQR/1.35, as 1.35 is the IQR (Inter-Quartile Range) of a standard normal distribution. The choice to use robust measures of location (median) and dispersion (IQR) was made to reduce the influence that cognitively impaired participants might have on the mean and SD, and in recognition of the slight negative skewness of the residuals. The robustly standardized residuals were then viewed as age-gender-education-visit-adjusted robust Z-scores for each of the five cognitive domains.

Defining aMCI/AD, Converters, and NC

For each subject, $Z_{\text{mem}}(\text{last})$, $Z_{\text{att}}(\text{last})$, $Z_{\text{exe}}(\text{last})$, $Z_{\text{lan}}(\text{last})$, and $Z_{\text{vis}}(\text{last})$ were defined as the age-gender-education-visit-adjusted robust Z-scores for the last available visit for each subject. We defined the aMCI/AD group to be those participants whose adjusted Z_{mem} was 1 IQR below the median at their last available visit, i.e. $Z_{\text{mem}}(\text{last}) \leq -1.35$. Converters were defined as that subset of the MCI/AD group whose adjusted Z_{mem} at baseline visit 0 was no more than 1 IQR below the median, i.e. $Z_{\text{mem}}(\text{visit}=0) > -1.35$ and $Z_{\text{mem}}(\text{last}) \leq -1.35$. Participants were classified as NC if they had central scores on all domains at both the first and last visits, i.e. only if they met all of the following six conditions: (i) $-1 < Z_{\text{mem}}(\text{last}) < 1$, (ii) $-1 < Z_{\text{mem}}(\text{visit}=0) < 1$, (iii) $Z_{\text{min}}(\text{last}) > -1.35$, (iv) $Z_{\text{min}}(\text{visit}=0) > -1.35$, (v) $Z_{\text{max}}(\text{last}) < 1.35$, and (vi) $Z_{\text{max}}(\text{visit}=0) < 1.35$, where $Z_{\text{max}}(\text{last})$ and $Z_{\text{max}}(\text{visit}=0)$ denote the maximum of the five adjusted Z-scores at the last and first visits, respectively. Z_{mem} for normal participants had to be within 0.74 IQR (1 SD) of the median, rather than just 1 IQR (1.35 SD), in order to guarantee that they were > 0.25 IQR (0.35 SD) from aMCI/AD participants.

Frequency matching aMCI/AD and NC on age, education, and sex

Comparing the distributions of age, education, and sex for participants classified as aMCI/AD and NC we observed that NC participants were younger. Given this, and given budget limitations for genetic profiling, we frequency matched NC participants to the aMCI/AD participants for each of the Discovery and Validation samples based on age, education, and sex. This was accomplished by stratifying the sample by four groups of age at the last visit (75-79, 80-85, 86-94, 95-100), three education groups (5-12, 13-18, 19-23), and two sexes (male, female), resulting in 24 age-education-sex strata. We randomly selected an equal number of NC participants to match the aMCI/AD participants per the strata for the Discovery sample and because one of the strata did not contain a sufficient number of NC participants, the Validation sample had one less NC subject than the aMCI/AD group.

Blood Collection, Shipment, and Specimen Processing Protocols

Collect Patient Vitals

1. Record date/time.
2. Collect and record height, weight, blood pressure, pulse and temperature.
3. Collect and record whether subject has had food/drink (except water) since midnight.
4. Record current medications/dosages.

Blood Draw

1. Draw 3 x 7 mL lavender top tubes and place on ice

Transfer Samples to Laboratory

1. Lavender top tubes should be shipped/transferred on blue ice packs or wet ice, but not frozen. Upon shipment arrival laboratory personnel will immediately process lavender top tube (see protocol below).

Shipment Protocol

Supplies: *paper tape for tube/bag sealing*
 absorbent material (paper towel)
 bubble wrap bag
 leakproof sealed bag

Styrofoam/sturdy outer box
gel packs
packing tape
“Exempt Human Specimen” labels

1. Keep lavender tubes after blood draw on ice (NOT FROZEN) prior to shipment.
2. Remove 2 small gel packs from freezer approximately 11/2 hours before shipping and **thaw to refrigerator temperature (~34 degrees)**
3. Seal each tube at stopper with paper tape. Leave folded end tab on tape for easier removal
4. Wrap each tube individually with absorbent material and place in bubble wrap bag. Seal with tape. Place all wrapped tubes in leakproof sealed plastic bag
5. Place cool/thawed gel packs in bottom of styrofoam box (with outer corrugated carton.) Lay wrapped lavender tube bags on thawed gel packs. (Do not want lavender top tubes to freeze.) Fill all void space with paper to prevent product movement
6. Include a copy of collection form (in plastic) inside cooler. Tape styrofoam cooler box top closed with packing tape
7. Include copy of delivery information on top of styrofoam cooler. Close and securely seal outer box with pressure-sensitive plastic tape. Apply packing tape over all flaps and seams
8. Ship all samples on same day, via **FedEx “Priority Overnight”** for Next Day Morning Delivery

Supplies - Blood Draw and Shipping

<u>Description</u>	<u>VWR Catalog Number and Price</u>	
VWR Koolit Gel 8oz CS72	33500-585	\$10.57
VWR Gel 16 oz. 6x6x1 CS36	33500-587	\$6.94
Container Molded 8x6x6.75 PK 12 (shipping box w/cooler)	33500-404	\$75.14
6x8 inch 3/16in bubble pouch CS250	80082-635	\$41.65
TC 6x9 ziploc bag pk 1000	80094-734	\$23.17

<u>Description</u>	<u>Cardinal Catalog Number and Price</u>	
7-ml Lavender Tube	B2991-52	\$8.74 / 100
Sterile Gauze	GZ2208-2	\$4.00 / 50
21 g butterfly w/ adapter	B3036-21	\$38.39 / 50
23 g butterfly w/ adapter	B3036-20	\$38.39 / 50
Vacutainer Holder for tubes	364815	\$5.49 / bag
Latex Free Bandages	BF3403	\$4.77 / 100
Alcohol prep pad	40000-110	\$1.39 / 200
Micropore tape	7246S	\$23.7 (12/box)
Specimen bag (w/ pouch)	49-96	\$32 / 1000

Plasma Specimen Processing Protocol

- 1) Remove paperwork and set of specimen tubes (3 lavender top tubes per patient) from package. Recycle package and contents
- 2) Place lavender tubes in 15 ml centrifuge bucket and balance. Keep specimen sets together
- 3) Spin tubes at 2600 RPM (1500 x g) for 10 minutes at 20°C (Program 2)
- 4) Remove tubes from centrifuge and place in Bio Hood by decontaminating with 70% EtOH
- 5) Remove the 50 ml tube caps for a **single specimen set** and place face down on underpad
- 6) Carefully remove the paper tape from the set of specimen lavender tubes corresponding to step 6. Next, remove purple caps by gently walking out the cap with Kimwipes. Place caps on stack of paper towels and save the Kimwipes

- 7) Collect plasma from each specimen tube with a 5 ml pipette (be careful not to disturb the buffy coat) and dispense into the 50 ml tube marked with a **P**. Recap P tube and place on ice.
- 8) Repeat steps 4 thru 7 as necessary for each specimen set
- 9) Remove P tube from ice and place in Bio Hood by decontaminating with 70% EtOH
- 10) Aliquot 25 μ l of plasma onto a square of parafilm. Draw aliquot into a microcuvette by capillary action.
Measure and record hemoglobin level using the HemoCue Photometer
- 11) Aliquot 750 μ l of plasma across the 2 ml pre-labeled plasma tubes until all of the collection is dispensed.
- 12) Place plasma aliquot 2 ml pre-labeled tubes into freezer rack.
- 13) Store the Plasma aliquots at -80°C .
